Constant step-size stochastic approximation with delayed updates

Aditya Mahajan, Silviu-Iulian Niculescu, and Mathukumalli Vidyasagar

Abstract— In this paper, we consider constant step-size stochastic approximation with delayed updates. For the non-delayed case, it is well known that under appropriate conditions, the discrete-time iterates of stochastic approximation track the trajectory of a continuous-time ordinary differential equation (ODE). For the delayed case, we show in this paper that, under appropriate conditions, the discrete-time iterates track the trajectory of a delay-differential equation (DDE) rather than an ODE. Thus, delayed updates lead to a qualitative change in the behavior of constant step-size stochastic approximation. We present multiple examples to illustrate the qualitative affect of delay and show that increasing the delay is generally destabilizing but, for some systems, it can be stabilizing as well.

Index Terms— stochastic approximation; iterative learning algorithms; time-delay systems

I. INTRODUCTION

Stochastic approximation refers to a family of iterative algorithms for finding the root of a function when only noisy function evaluations are available [1]. Formally, given a real function $f \colon \mathbb{R}^p \to \mathbb{R}$ and an initial value $\theta_0 \in \mathbb{R}^p$, consider the iteration

$$\theta_{n+1} = \theta_n + \alpha_n \big[f(\theta_n) + \xi_{n+1} \big], \quad n \geq 0 \qquad (1)$$

where $\{\xi_{n+1}\}_{n \geq 1}$ is a noise process, $\{\alpha_n\}_{n \geq 1}$ is the learning rate process, and $f \colon \mathbb{R}^p \to \mathbb{R}$ is a continuous function. Stochastic approximation theory identifies conditions under which the iteration (1) converges almost surely, with high probability, or in the mean-squared sense. We refer the reader to [2]–[4] for an overview. Stochastic approximation theory is the building block of many of modern machine learning methods including system identification [5], [6], adaptive control [7], [8], reinforcement learning [9], and others.

Time heterogeneity is an important feature in a large variety of applications where transport and propagation phenomena and/or communication constraints have to be considered. In such cases, the noisy evaluation of the function is not available instantaneously but only after a delay. Examples include delay in biological systems, delay in

financial markets, delay in feedback communication systems, delay in reward feedback in learning algorithms, etc. For instance, there is a lot of recent interest in multi-armed bandits (MAB) and reinforcement learning (RL) when there is a delay between taking an action and receiving a reward. Several variations of MAB with delayed reward feedback have been considered [10]–[19]. However, the literature on RL with delayed reward feedback is more limited [20]–[23] and a general theory characterizing the fundamental limits of convergence of RL with delayed reward feedback is still lacking.

In such settings, it is important to understand the convergence properties of the iteration

$$\theta_{n+1} = \theta_n + \alpha_n \big[f(\theta_{n-d}) + \xi_{n+1} \big], \quad n \geq d \qquad (2)$$

where $d \in \mathbb{Z}_{\geq 0}$ corresponds to the *processing delay*. We call this iteration *stochastic approximation with delayed updates*. For the case of $d = 0$, it reduces to the standard stochastic approximation. In this paper, we focus on the setting where the step size $\alpha_n = \alpha$ is *constant*. The standard approach to analyze such models when delay $d = 0$ is the so called *ODE approach*, which was initiated in the 1970s by Ljung [24] and extensively developed during the last 40 years, see, e.g. [3], [4], [25] and the references therein. Stochastic approximation with constant step size is useful for analysis of reinforcement learning algorithms [26] and evolutionary games and population dynamics [27], [28]. Finally, for some discussions on an optimal choice of the constant step size, we refer to [29].

The main contribution of the paper is twofold: first, we extend the *ODE approach* for the analysis of stochastic approximation to the delay case. More precisely, we will show that in the case of constant step-size, the long-term qualitative behavior of the above process is "close" to the behavior of the solutions of an appropriate delay-differential equation (DDE)[1] and thus the exponential stability of the corresponding DDE will allow concluding on the convergence properties of the stochastic approximation under consideration. The results are proposed in the case of a single delay and extend to multiple delays by following the same arguments. To the best of our knowledge, such a result represents a novelty in the literature.

Second, we show the way in which the delay, seen as a *parameter*, affects the corresponding convergence properties. More precisely, we show that increasing the delay has a dichotomic character: generally, increasing the delay has a destabilizing effect but, under some conditions, increasing

[1]We refer the reader to [30], [31] for an overview of DDEs.

(a) Delay $d = 0$ (b) Delay $d = 2$
(c) Delay $d = 4$ (d) Delay $d = 8$

Fig. 1: Iterates for Example 1 for different values of delay.

the delay may have a stabilizing effect as well. Such a property is largely discussed in the analysis and control of time-delay systems, see, e.g. [31]–[35] and the references therein and we believe that it opens interesting perspectives in stochastic approximation that need to be further explored.

In contemporaneous work, [36] have also investigated constant step-size stochastic approximation with delayed updates. They focus on finite time convergence guarantees and, therefore, their proof techniques and the nature of results are different than ours.

The remaining of the paper is organized as follows: Sec. II includes a motivating example, prerequisites and some basic results in the stability analysis of DDEs. The convergence analysis of the constant step-size approximation in the case of single delays is proposed in Sec. III. Next, the proposed results are illustrated on an application involving multiple delays in Sec. IV. Finally, some concluding remarks end the paper. The notations are standard and explained when first used.

II. A MOTIVATING EXAMPLE AND BACKGROUND

To fix ideas, we present a simple example to illustrate why delay may cause a qualitative difference in the behavior of stochastic approximation.

Example 1 Consider iteration (2) for $\theta_n \in \mathbb{R}$ with $\alpha_n = \alpha = 0.1$ and

$$f(\theta) = -\kappa\theta, \quad \text{where} \quad \kappa = 2.5 \quad \text{and} \quad \xi_{n+1} \sim \mathcal{N}(0, 0.5).$$

We plot the iterates θ_n for different values of delay d. We run each simulation for $N = 100$ steps and repeat the simulation for $M = 25$ sample paths. For each sample path, the initial conditions $\theta_{1:d}$ are chosen such that θ_n, $n \in \{0, 1, \ldots, d\}$, are independently sampled from Unif$[-1, 1]$. The results are shown in Figure 1.

The plots show that when the delay is small, the iterates are stable and converge to zero. However, as the delay

increases, the iterates become unstable and diverge. ***Thus, delay may quantitatively change the behavior of stochastic approximation.***

To understand why this is the case, recall that the standard stochastic approximation iteration (1) may be viewed as a noisy Euler discretization of the continuous time ODE (ordinary differential equation)

$$\dot{\theta}(t) = f(\theta(t)). \tag{3}$$

Therefore, under appropriate regularity conditions, the iterates of (1) converge to the equilibrium points of (3). By analogy, one may view the iterations (2) of stochastic approximation with delay as a noisy Euler discretization of the continuous-time DDE (delay-differential equation) of retarded type[2]

$$\dot{\theta}(t) = f(\theta(t - \tau)), \quad \text{where } \tau = \alpha d. \tag{4}$$

Therefore, one would expect that under appropriate regularity conditions, the iterates of (2) should converge to the equilibrium points of (4).

For Example 1, Eq. (4) is a linear DDE:

$$\dot{\theta}(t) + \kappa\theta(t - \tau) = 0, \quad \text{where } \kappa = 2.5, \tau = 0.1d. \tag{5}$$

To understand the behavior of this DDE, we review basic stability results [30], [31] for linear DDEs of the form

$$\dot{\theta}(t) = A\theta(t - \tau), \quad \text{where } \theta \in \mathbb{R}^p, A \in \mathbb{R}^{p \times p}. \tag{6}$$

The characteristic function $f : \mathbb{C} \times \mathbb{R}_+^* \mapsto \mathbb{C}$ of (6) is given by

$$f(\lambda; \tau) = \det\left(\lambda I_p - A e^{-\lambda\tau}\right), \tag{7}$$

which is a quasipolynomial of *retarded* type[3]. Let $\{\lambda_i(A)\}_{i=1}^p$ denote the eigenvalues of A, with $|\lambda_i(A)|$ and $\angle\lambda_i(A)$ denoting their modulus and argument, respectively.

With the notations above, we have the following result (see [31] for details):

Lemma 1 *Under the assumption that A is a Hurwitz matrix, the trivial solution of the DDE (6) is exponentially stable if and only if the delay $\tau \in [0, \tau_\circ)$, where $\tau_\circ$ is given by:*

$$\tau_\circ = \min_{i \in \{1, \ldots, p\}} \frac{\omega_i}{|\lambda_i(A)|}, \tag{8}$$

where $\omega_i = \min(\mathcal{A}_i^+)$ denotes the smallest positive value of the (non-empty) set $\mathcal{A}_i^+$ given by:

$$\mathcal{A}_i^+ = \mathbb{R}_+^* \cap \left\{-\frac{\pi}{2} + \angle\lambda_i(A) + 2\ell\pi : \ell \in \mathbb{Z}\right\},$$

for $i \in \{1, \ldots p\}$.

For the scalar case (5), $A = -\kappa$ (with $\kappa > 0$). So, $\lambda_1 = -\kappa = \kappa e^{i\pi}$, and $\omega_1 = \pi/2$ is the smallest positive element of the set $\mathcal{A}_1^+$. Thus, the system (4) is stable when delay $\tau = \alpha d < \tau_\circ := \pi/(2\kappa)$; thus

$$\alpha d < \frac{\pi}{2\kappa}. \tag{9}$$

---

[2]For a classification of DDEs, the reader is referred to [37]; Throughout this paper, all the DDEs based-models are of retarded type.

[3]including only point spectrum, see, e.g. [31]

(a) Delay $d = 6$ (b) Delay $d = 7$

Fig. 2: Iterates for Example 1 for different values of delay close to critical delay for $\alpha = 0.1$.

(a) Delay $d = 62$ (b) Delay $d = 63$

Fig. 3: Iterates for Example 1 for different values of delay close to critical delay for $\alpha = 0.01$.

The above bound is derived based on the approximate equivalence between the discrete-time iterates and the Euler discretization of the continuous time DDE, which is valid only for small values of α. It turns out that $\alpha = 0.1$ that we picked in Example 1 is not sufficiently small. For that value of α, (9) implies that the system is stable as long as $d < d_\circ \coloneqq \pi/(2\alpha\kappa) = 6.283$. However, this is not the case as can be seen by the plots shown in Figure 2 for $d = \lfloor d_\circ \rfloor = 6$ and $d = \lceil d_\circ \rceil = 7$. However, if we pick a smaller value of α, say $\alpha = 0.01$, and rerun the simulation for $d = \lfloor d_\circ \rfloor = 62$ and $d = \lceil d_\circ \rceil = 63$, the results (shown in Figure 3) are consistent with the theoretical intuition.

In Sec. III, we identify general set of conditions under which the constant step-size stochastic approximation with delayed updates (2) converges.

In the example presented above, delay has a *destabilizing effect*, i.e., increasing the delay destabilizes the system. In general, delay can also have a stabilizing effect, i.e., increasing the delay stabilizes the system! In Sec. IV, we present an application which gives rise to stochastic approximation with two delay blocks and present a numerical example which highlights the stabilizing impact of delay.

III. CONVERGENCE ANALYSIS OF CONSTANT STEP-SIZE STOCHASTIC APPROXIMATION WITH SINGLE DELAY

In this section, we consider stochastic approximation with delayed updates (2) when the step size is constant, i.e., $\alpha_n = \alpha$ for all n. The following assumptions are imposed on the model.

(A1) There exists a root θ^* of $f(\theta) = 0$.

(A2) The function f is Lipschitz continuous with a Lipschitz constant $\|f\|_L < \infty$.

(A3) The noise $\{\xi_n\}_{n \geq 1}$ is a martingale difference sequence with respect to $\bar{\mathcal{F}}_n = \sigma(\theta_{1:n}, \xi_{1:n})$, i.e.,

$$\mathbb{E}[\xi_{n+1} \mid \mathcal{F}_n] = 0.$$

Moreover, $\{\xi_n\}_{n \geq 1}$ is square integrable with

$$\mathbb{E}[\|\xi_n\|^2 \mid \mathcal{F}_n] \leq C_\xi(1 + \|\theta_n\|^2), \quad \text{a.s.}, n \geq 1,$$

where $C_\xi < \infty$ is a constant.

(A4) θ^* is the unique solution of $f(\theta) = 0$ and is also the global asymptotically stable equilibrium point of DDE (4).

(A5) The process $\sup_{k \in \{-d+1,\ldots,0\}} \|\theta_{n+k}^2\|^2$ is uniformly integrable, i.e., there exists a constant $C_\theta < \infty$ and a Borel function[4] $G \colon [0, \infty) \to [0, \infty)$ satisfying $G(x)/x \to \infty$ when $x \to +\infty$ such that

$$\sup_{n \geq 1} \mathbb{E}\left[\sup_{k \in \{-d+1,\ldots,0\}} \|\theta_{n+k}\|^2\right]^{\frac{1}{2}} \leq C_\theta$$

and

$$\sup_{n \geq 1} \mathbb{E}\left[G\left(\sup_{k \in \{-d+1,\ldots,0\}} \|\theta_{n+k}^2\|^2\right)\right] < \infty.$$

Assumptions (A1)–(A3) are standard in the analysis of stochastic approximation [3]. Assumption (A4) is the natural analog of the corresponding stability assumption in the ODE analysis of stochastic approximation [3]. Assumption (A5) ensures that the iterates $\{\theta_n\}_{n \geq 0}$ remain stable. In principle, it is possible to relax this assumption by assuming the global asymptotic stability of an appropriately scaled DDE, following the ideas of [26], but we defer such a relaxation to future work.

For the ease of notation, we will assume that the coordinate system is chosen such that $\theta^* = 0$; i.e., under (A1), $f(0) = 0$ and under (A4), origin is global asymptotically stable solution of the DDE (4).

The high-level idea is similar to the convergence analysis of standard stochastic approximation with constant step size [3] with appropriate changes to account for the fact that the discrete-time process is tracking a DDE rather than an ODE. We start with the construction of two continuous time processes $\{\Theta(t)\}_{t \in \mathbb{R}_{\geq 0}}$ and $\{\vartheta^{(s)}(t)\}_{t \in \mathbb{R}_{\geq 0}}$ that track the discrete-time iterates $\{\theta_n\}_{n \geq 0}$ in an appropriate sense. In order to define these processes, we define the map $t(n) = n\alpha, n \geq 0$, which translates discrete-time to continuous-time. Let $\tau = d\alpha$ be the continuous-time processing delay.

- The process $\{\Theta(t)\}_{t \in \mathbb{R}_{\geq 0}}$ is a piecewise linear and continuous process which is defined to be equal to θ_n at time $t(n)$, $n \in \mathbb{Z}_{\geq 0}$, and is a linear interpolation between θ_n and θ_{n+1} at times in the open interval $(t(n), t(n+1))$.

- For any $t_0 \in \mathbb{R}_{\geq 0}$, the process $\{\vartheta^{(t_0)}(t)\}_{t \geq t_0}$ is the solution of the DDE (4), starting at time t_0 with the initial conditions $\vartheta^{(t_0)}(t_0 + s) = \Theta(t_0 + s)$, $s \in [-\tau, 0]$.

These processes are close to each other in the following sense.

---

[4]sometimes called *test function* of uniform integrability

Lemma 2 *For any initial time $t_0 \in \mathbb{R}_{\geq 0}$ and horizon $T \in \mathbb{R}_{\geq 0}$, we have*

$$\mathbb{E}\left[\sup_{t \in [0,T]}\left\|\Theta(t_0+t) - \vartheta^{(t_0)}(t_0+t)\right\|^2\right] \in \mathcal{O}(\alpha). \quad (10)$$

PROOF The proof relies on the fact that when $f(\cdot)$ is Lipschitz the solution of DDE (4) is Lipschitz in finite time due to Gronwall-Halanay inequality [38], [39] (see Appendix A) and that under Assumption (A3) the cumulative error cause by the noise process $\{\xi_{n+1}\}_{n \geq 1}$ is bounded due to Burkholder's inequality [40]. The details are omitted due to space limitations. ∎

We introduce the following notations:

- For a discrete-time sequence $\{x_n\}_{n > -d}$,

$$[\![x_n]\!] := \sup_{k \in \{-d+1,\ldots,0\}} \|x_{n+k}\|.$$

- For a continuous-time signal $\{x(t)\}_{t \geq -\tau}$,

$$[\![x_t(\cdot)]\!] := \sup_{s \in [-\tau,0]} \|x(t+s)\|.$$

By Assumption (A5), $[\![\theta_n]\!]^2$ is uniformly integrable. Therefore, there exists a positive real R such that

$$\sup_{n \geq 1} \mathbb{P}([\![\theta_n]\!] \geq R) < \alpha, \quad (11a)$$

$$\sup_{n \geq 1} \mathbb{E}\left[[\![\theta_n]\!]^2 \mathbb{1}\{[\![\theta_n]\!] \geq R\}\right] < \alpha. \quad (11b)$$

By construction, $[\![\Theta_{t(n)}(\cdot)]\!] = [\![\theta_n]\!]$. So, equation (11) also holds when $[\![\theta_n]\!]$ is replaced by $[\![\Theta_{t(n)}(\cdot)]\!]$.

By Assumption (A4), we can pick a $T = N\alpha$ large enough such that any solution $\vartheta(\cdot)$ of (4) starting with an initial $\vartheta(s)$, $s \in [-\tau, 0]$ with $\vartheta(0) \neq 0$, where $[\![\vartheta_0(\cdot)]\!] \leq R$ has the property that

$$[\![\vartheta_T(\cdot)]\!] \leq \tfrac{1}{2}[\![\vartheta_0(\cdot)]\!]. \quad (12)$$

Lemma 3 *We have that for all $t \geq 0$,*

$$\mathbb{E}\left[[\![\Theta_{t+T}(\cdot)]\!]^2 \mathbb{1}\{[\![\Theta_t(\cdot)]\!] \leq \sqrt{\alpha}\}\right]^{\frac{1}{2}} \in \mathcal{O}(\sqrt{\alpha}), \quad (13)$$

$$\mathbb{E}\left[[\![\Theta_{t+T}(\cdot)]\!]^2 \mathbb{1}\{[\![\Theta_t(\cdot)]\!] > R\}\right]^{\frac{1}{2}} \in \mathcal{O}(\sqrt{\alpha}). \quad (14)$$

PROOF To show the first part, we observe that

$$\mathbb{E}\left[[\![\Theta_{t+T}(\cdot)]\!]^2 \mathbb{1}\{[\![\Theta_t(\cdot)]\!] \leq \sqrt{\alpha}\}\right]^{\frac{1}{2}}$$
$$\overset{(a)}{\leq} \mathbb{E}\left[([\![\vartheta^{(t)}_{t+T}(\cdot)]\!]^2 + \mathcal{O}(\alpha))\mathbb{1}\{[\![\Theta_t(\cdot)]\!] \leq \sqrt{\alpha}\}\right]^{\frac{1}{2}}$$
$$\overset{(b)}{\leq} \tfrac{1}{2}\sqrt{\alpha} + \mathcal{O}(\sqrt{\alpha}) \in \mathcal{O}(\sqrt{\alpha}) \quad (15)$$

where (a) follows from Lemma 2 and (b) follows from (12) and our choice of T.

To show the second part, we observe that

$$\mathbb{E}\left[[\![\Theta_{t+T}(\cdot)]\!]^2 \mathbb{1}\{[\![\Theta_t(\cdot)]\!] > R\}\right]^{\frac{1}{2}}$$
$$\overset{(c)}{\leq} \mathbb{E}\left[([\![\vartheta^{(t)}_{t+T}(\cdot)]\!]^2 + \mathcal{O}(\alpha))\mathbb{1}\{[\![\Theta_t(\cdot)]\!] > R\}\right]^{\frac{1}{2}}$$
$$\overset{(d)}{\leq} \mathbb{E}\left[K[\![\Theta_t(\cdot)]\!]^2 \mathbb{1}\{[\![\Theta_t(\cdot)]\!] > R\}\right]^{\frac{1}{2}} + \mathcal{O}(\sqrt{\alpha})$$
$$\overset{(e)}{\leq} K\sqrt{\alpha} + \mathcal{O}(\sqrt{\alpha}) \in \mathcal{O}(\sqrt{\alpha}) \quad (16)$$

where (c) follows from Lemma 2 and (d) follows from Gronwall-Halanay inequality (see Appendix A) and K is a T dependent constant, and (e) follows from (11) and our choice of R. ∎

Theorem 1 *We have that*

$$\limsup_{n \to \infty} \mathbb{E}[\|\theta_n\|^2]^{\frac{1}{2}} \in \mathcal{O}(\sqrt{\alpha}). \quad (17)$$

Therefore, for any $\varepsilon > 0$, we have

$$\limsup_{n \to \infty} \mathbb{P}(\|\theta_n\| > \varepsilon) \in \mathcal{O}(\alpha). \quad (18)$$

PROOF Take an arbitrary n and let $t_0 = t(n)$. Then,

$$\mathbb{E}[[\![\theta_{n+N}]\!]^2]^{\frac{1}{2}}$$
$$= \mathbb{E}[[\![\Theta_{t_0+T}(\cdot)]\!]^2]^{\frac{1}{2}}$$
$$\leq \mathbb{E}[[\![\Theta_{t_0+T}(\cdot)]\!]^2 \mathbb{1}\{[\![\Theta_{t_0}(\cdot)]\!] \leq \sqrt{\alpha}\}]^{\frac{1}{2}}$$
$$\quad + \mathbb{E}[[\![\Theta_{t_0+T}(\cdot)]\!]^2 \mathbb{1}\{\sqrt{\alpha} < [\![\Theta_{t_0}(\cdot)]\!] \leq R\}]^{\frac{1}{2}}$$
$$\quad + \mathbb{E}[[\![\Theta_{t_0+T}(\cdot)]\!]^2 \mathbb{1}\{[\![\Theta_{t_0}(\cdot)]\!] > R\}]^{\frac{1}{2}}$$
$$\overset{(a)}{\leq} \mathbb{E}[[\![\Theta_{t_0+T}(\cdot)]\!]^2 \mathbb{1}\{\sqrt{\alpha} < [\![\Theta_{t_0}(\cdot)]\!] \leq R\}]^{\frac{1}{2}} + \mathcal{O}(\sqrt{\alpha})$$
$$\overset{(b)}{\leq} \mathbb{E}[[\![\vartheta^{(t_0)}_{t_0+T}(\cdot)]\!]^2 \mathbb{1}\{\sqrt{\alpha} < [\![\Theta_{t_0}(\cdot)]\!] \leq R\}]^{\frac{1}{2}} + \mathcal{O}(\sqrt{\alpha})$$
$$\overset{(c)}{\leq} \tfrac{1}{2}\mathbb{E}[[\![\Theta_{t_0}(\cdot)]\!]^2]^{\frac{1}{2}} + \mathcal{O}(\sqrt{\alpha})$$
$$= \tfrac{1}{2}\mathbb{E}[[\![\theta_n]\!]^2]^{\frac{1}{2}} + \mathcal{O}(\sqrt{\alpha}) \quad (19)$$

where (a) follows from Lemma 3, (b) follows from Lemma 2, and (c) follows from (12) and the choice of T.

Let the constant corresponding to the $\mathcal{O}(\sqrt{\alpha})$ term in (19) be K. Now consider

$$\mathbb{E}[[\![\theta_{n+2N}]\!]^2]^{\frac{1}{2}} \leq \tfrac{1}{2}\mathbb{E}[[\![\theta_{n+N}]\!]^2]^{\frac{1}{2}} + K\sqrt{\alpha}$$
$$\leq \tfrac{1}{4}\mathbb{E}[[\![\theta_{n+N}]\!]^2]^{\frac{1}{2}} + K(1 + \tfrac{1}{2})\sqrt{\alpha} \quad (20)$$

where both inequalities follow from (19). Continuing this way, we can show that for any positive integer k

$$\mathbb{E}[[\![\theta_{n+kN}]\!]^2]^{\frac{1}{2}}$$
$$\leq (\tfrac{1}{2})^k \mathbb{E}[[\![\theta_{n+N}]\!]^2]^{\frac{1}{2}} + K(1 + \tfrac{1}{2} + \cdots + \tfrac{1}{2^{k-1}})\sqrt{\alpha}. \quad (21)$$

Therefore,

$$\limsup_{k \to \infty} \mathbb{E}[\|\theta_{n+kN}\|^2]^{\frac{1}{2}} \leq 2K\sqrt{\alpha}. \quad (22)$$

Recall that n was chosen arbitrarily. By repeating the above argument for $n+1$, $n+2$, …, $n+N-1$, in place of n, we get

$$\limsup_{n \to \infty} \mathbb{E}[[\![\theta_n]\!]^2]^{\frac{1}{2}} \in \mathcal{O}(\sqrt{\alpha}) \quad (23)$$

Eq. (17) then follows from the simple observation that $\|\theta_n\| \leq [\![\theta_n]\!]$. Finally, (18) is a direct consequence of Chebyshev's inequality. ∎

IV. AN APPLICATION

Consider the problem of fine-tuning a machine learning model on a mobile device connected to a cloud server. For the purpose of this section, we abstract this problem to finding the zero of a function $f : \mathbb{R}^p \to \mathbb{R}$. At each time n, the mobile device and the cloud server are asked to provide an estimate of $f(\theta_n)$. The mobile device provides a "quick and dirty" answer while the cloud server provides a "slow and precise" answer. We model this situation by assuming that the mobile device (which we index by 1) returns the evaluation $f(\theta_n)$ at time $n + d_1$ with noise level $w_{1,n-d_1+1}$, while the cloud server (which we index by 2) returns the evaluation of $f(\theta_n)$ at time $n + d_2$ with noise level $w_{2,n-d_2+1}$, where d_1 is smaller than d_2 but the variance of $w_{1,n}$ is more than the variance of $w_{2,n}$. The computational bandwidth on the two devices is not limited. That is, if the mobile device and the cloud server have inputs θ_n and θ_{n+1} at times n and $n+1$, they will generate outputs at time $n + d_i$ and $n + d_i + 1$.

Both these evaluations are combined together as follows:

$$\theta_{n+1} = \theta_n + \alpha_1 \big[f(\theta_{n-d_1}) + w_{1,n-d_1+1} \big] \\ + \alpha_2 \big[f(\theta_{n-d_2}) + w_{2,n-d_2+1} \big], \quad (24)$$

where we assume that the noise processes $\{w_{1,n}\}_{n \geq 1}$ and $\{w_{2,n}\}_{n \geq 2}$ are i.i.d. processes that are mutually independent. For the ease of notation, we take $\alpha_1 = \alpha$ and $\alpha_2 = \gamma\alpha$, and write the above iteration as

$$\theta_{n+1} = \theta_n + \alpha \big[f(\theta_{n-d_1}) + \gamma f(\theta_{n-d_2}) + \xi_{n+1} \big] \quad (25)$$

where $\xi_{n+1} = w_{1,n-d_1+1} + \gamma w_{2,n-d_2+1}$.

Following an argument similar to Sec. III, we can show that the result of Theorem 1 is also true for iteration (25), provided assumption (A4) is replaced by the following:

(A4a) θ^* is the unique solution of $f(\theta) = 0$ and is also global asymptotically stable equilibrium point of the DDE

$$\dot{\theta}(t) = f(\theta(t - \tau_1) + \gamma f(\theta(t - \tau_2)) \quad (26)$$

where $\tau_1 = \alpha d_1$ and $\tau_2 = \alpha d_2$.

Eq. (26) is a DDE with two delay blocks. We now provide two examples to illustrate the impact of the delays d_1 and d_2 and the *gain* γ on the stability of (26).

A. Scalar example with two delay blocks

Example 2 Consider iteration (25) for $\theta_n \in \mathbb{R}$ with

$$f(\theta) = -\tfrac{1}{2}\kappa\theta \quad \text{and} \quad \gamma = 1.$$

In this case, the corresponding DDE (26) is

$$\dot{\theta}(t) = -\frac{\kappa}{2} \big[\theta(t - \alpha d_1) + \theta(t - \alpha d_2) \big], \quad (27)$$

where $0 \leq d_1 < d_2$. In this case, the delays are commensurate[5], therefore the exponential stability of (27) is guaranteed all $\alpha \in [0, \alpha_\circ)$, with:[6]

$$\alpha_\circ = \left[d_1 \kappa \, \mathrm{sinc} \left(\frac{\pi}{1 + d_2/d_1} \right) \right]^{-1}$$

---

[5]i.e., there is rational dependence between the delay parameters
[6]See [30], [31] for details on the analysis of such linear DDEs.

---

where $\mathrm{sinc}(x) = (\sin x)/x$. Furthermore, the system is unstable for all $\alpha > \alpha_\circ$.

We consider a few special cases below.

- Consider $d_1 = d_2 = d$. In this case, $\alpha_\circ = \pi/(2d\kappa)$. Thus, the system (27) is stable if and only if $\alpha < \pi/(2d\kappa)$ or, equivalently, $d < d_\circ := \pi/(2\alpha\kappa)$. This recovers the result for Example 1.

- Consider $d_1 = 1$ and $d_2 = d$. In this case, the system (27) is stable if and only if

$$\alpha < \frac{1}{\kappa \, \mathrm{sinc}\left(\dfrac{\pi}{1+d} \right)}.$$

Note that the right hand side is a decreasing function of d and converges to the limit $1/\kappa$ as $d \to \infty$ (one can verify this using L'Hôpital's rule). Thus, if $\alpha < \alpha_\circ := 1/\kappa$, then the system (27) is always stable for any value of d. If $\alpha > \alpha_\circ$, then there is a critical delay

$$d_\circ := \left\lfloor \frac{\pi}{\mathrm{sinc}^{-1}(\alpha\kappa)} - 1 \right\rfloor$$

such that (27) is stable for all delay $d < d_\circ$ and is unstable for $d > d_\circ$.

Thus, for the case of two delay blocks with the same gain and commensurate delays, the delay has a has a *destabilizing* effect, as was the case for Example 1 In the next section, we present an example for a vector system and show that delay can have a *stabilizing* impact.

B. Vector example with two delay blocks

Example 3 Suppose we are interested in finding the fixed point of $f(\theta) = A\theta$ based on different delayed evaluations of $f(\theta)$. We assume that we combine the two evaluations as follows

$$\theta_{n+1} = \theta_n + \alpha \big[A\theta_{n-d_1} + w_{1,n-d_1+1} \big] \\ + \alpha\Gamma \big[A\theta_{n-d_2} + w_{2,n-d_2+1} \big] \quad (28)$$

where $\Gamma \in \mathbb{R}^{p \times p}$.

The equivalent of assumption (A4a) in this case is the following:

(A4b) θ^* is the unique solution of $f(\theta) = 0$ and also global asymptotically stable equilibrium point of the DDE

$$\dot{\theta}(t) = A\theta(t - \tau_1) + \Gamma A\theta(t - \tau_2), \quad (29)$$

where $\tau_1 = \alpha d_1$ and $\tau_2 = \alpha d_2$.

Consider the special case where $p = 2$, $d_1 = 0$, $d_2 = d > 1$, and:

$$A = \begin{bmatrix} 0 & -\omega_\circ^2 \\ 1 & 0 \end{bmatrix} - \kappa I, \quad \Gamma = \begin{bmatrix} 0 & 0 \\ 0 & -\gamma \end{bmatrix}.$$

where $\gamma, \omega_\circ \in \mathbb{R}_+^*$. Thus, the DDE (29) is equivalent to

$$\dot{\theta}(t) = A\theta(t) + \Gamma A\theta(t - \tau) \\ = \begin{bmatrix} -\kappa & -\omega_\circ^2 \\ 1 & -\kappa \end{bmatrix} \theta(t) + \begin{bmatrix} 0 & 0 \\ -\gamma & \gamma\kappa \end{bmatrix} \theta(t - \tau) \quad (30)$$
Fig. 4: Interpretation of $\Delta(\lambda)$ in (31) as the characteristic of a closed loop SISO system with time-delays.

where $\tau = \alpha d$. The characteristic function of the DDE (30) $\Delta : \mathbb{C} \mapsto \mathbb{C}$ is given by:

$$\Delta(\lambda) := \lambda^2 + 2\lambda k + k^2 + \omega_\circ^2 - \gamma e^{-\lambda \tau}(k^2 + \lambda k + \omega_\circ^2). \quad (31)$$

It is easy to see that Δ can be interpreted as the closed-loop characteristic function of a transfer LTI SISO function

$$H_{yu}(\lambda) = \frac{\lambda k + k^2 + \omega_\circ^2}{\lambda^2 + 2\lambda k + k^2 + \omega_\circ^2}$$

of relative degree one controlled by a delay block $(-\gamma, \tau)$ as shown in Figure 4. In the case of low damping (κ), depending of the gain value γ, the closed-loop system free of delay is exponentially stable and we will have a finite sequence of delay intervals guaranteeing the stability of the closed-loop system. More precisely, if we consider the *spectral abscissa*[7] as a function of the delay parameter, it is continuous, finite and bounded function in the case of dynamical systems represented by DDEs of retarded type. For more details on the properties of the spectral abscissa, we refer to [31] and the references therein. In our example, we have 2 crossing frequencies $0 < \omega_- < \omega_+$ which are independent of the delay values: ω_+ corresponds to characteristic roots crossing the imaginary axis towards instability and ω_- in the opposite direction if the delay (parameter) is increasing in $\mathbb{R}_+$. Furthermore, as mentioned in [31], the crossing directions at $\omega_\pm$ are independent of the delay parameter.

These crossing roots define a partition of the delay-parameter space $\mathbb{R}_+$ in a sequence of stable delay intervals (τ_i^-, τ_{i+1}^+), and unstable delay intervals $(\tau_{i+1}^+, \tau_{i+2}^-)$, for a positive, but finite integer $i \geq 1$. Such a procedure is called τ-*decomposition method* and was introduced by Lee and Hsu [41] at the end of the 1960s and it is at the origin of several approaches and procedures largely reported in the literature (see, e.g., [31], [33], [34] and the references therein).

In our case study, the first delay interval has the form $[0, \tau_1^+)$ where τ_1^+ represents the delay margin. Thus, to conclude, the continuous dynamical system is stable if

$$\alpha d = \tau \in [0, \tau_1^+) \cup (\tau_2^-, \tau_3^+) \cup \cdots$$

As an illustrative example, suppose $\gamma = 0.3$ and $\kappa = \gamma/4$, then the root locus is shown in Figure 5[8] with

$$\tau_1^+ = 3.4015, \quad \tau_2^- = 6.9064, \quad \tau_3^+ = 9.0049, \quad \text{etc.}$$

[7]The *spectral abscissa* is defined by the real part of the rightmost root of the characteristic function [31].

[8]The authors wish thank CÉSAR FERNANDO MÉNDEZ-BARRIOS (UASLP, Mexico) and DIEGO TORRES-GARCIA (UASLP, MEXICO & UPSAY, FRANCE) for their help in generating the graphical representation.

Fig. 5: Characteristic roots as a function of the delay parameter $\tau \in [0, 15]$: the black plot corresponds to the first crossing towards instability at the frequency ω_+ and back to stability at the frequency ω_- defining thus the first unstable delay interval (τ_1^+, τ_2^-); the red plot corresponds to the second crossing towards instability at the frequency ω_+ and back to stability at the frequency ω_- defining the second unstable delay interval (τ_3^+, τ_4^-), etc.

Note larger delays stabilize the system showing the so-called *stabilizing* effect induced by the delay, seen as a parameter. For a better understanding of such a mechanism as well as a more detailed analysis of of the delay effects, we refer to [31], [35] and the references therein.

V. CONCLUSION

In this paper, we considered constant step-size stochastic approximation with delayed updates. Our main observation is that under appropriate conditions, the discrete-time iterates of stochastic approximation with delayed updates

$$\theta_{n+1} = \theta_n + \alpha[f(\theta_{n-d}) + \xi_{n+1}]$$

track the continuous-time trajectory of a DDE (as opposed to an ODE)

$$\dot{\theta}(t) = f(\theta(t - \tau)), \quad \tau = \alpha d.$$

The result was derived under several technical conditions; the most critical being (A4) which asserts that the DDE should be global asymptotically stable and (A5) which asserts that the discrete-time iterates are uniformly integrable. There are several results in time-delay systems to verify the stability of DDEs. Typically, the DDE is stable for values of $\tau = \alpha d$ belonging to a union of disjoint intervals. This shows that there is a trade-off between the learning rate α and the delay d. Verifying (A5) is harder. It may be possible to generalize the scaled ODE approach of [26] to derive sufficient conditions to verify (A5), which may be an interesting future research direction.

Appendix A
Gronwall-Halanay inequality

We first state Gronwall's inequality, which is the standard result used for determining the sensitivity of a differential equation to its initial conditions.

Lemma 4 (Gronwall inequality) *Suppose that the continuous functions* $u, \kappa \colon [0, T] \to [0, \infty)$ *and* $K > 0$ *satisfy*

$$u(t) \leq K + \int_0^t \kappa(s) u(s) \, ds$$

for all $t \in [0, T]$. *Then*

$$u(t) \leq K \exp \left(\int_0^t \kappa(s) \, ds \right).$$

Now we extend the inequality to delay differential equations. Variations of this inequality are referred to as Hanalay inequalities [38], [39].

Lemma 5 (Gronwall-Hanalay inequality) *Given a delay $\tau \geq 0$, suppose that the continuous functions $u\colon [-\tau, T] \to [0, \infty)$ and $\kappa\colon [0, T] \to [0, \infty)$ and $K > 0$ satisfy*

$$u(t) \leq K + \int_0^t \kappa(s)u(s - \tau)\, ds \qquad (32)$$

for all $t \in [0, T]$. Then

$$u(t) \leq K \exp\left(\int_0^t \kappa(s)\, ds\right) \qquad (33)$$

PROOF Let $[\![u(t)]\!] = \sup_{s \in [-\tau, 0]} u(t + s)$. Then, since $u(s) \geq 0$, Eq. (32) may be written as

$$u(t) \leq K + \int_0^t \kappa(s)[\![u(s)]\!]\, ds \qquad (34)$$

Furthermore, observe that the right hand side of (34) is increasing in t. Therefore,

$$[\![u(t)]\!] \leq K + \int_0^t \kappa(s)[\![u(s)]\!]\, ds. \qquad (35)$$

Therefore, by Gronwall inequality, we have

$$[\![u(t)]\!] \leq K \exp\left(\int_0^t \kappa(s)\, ds\right)$$

which implies the result. ∎
